L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

# Analogies and Theories: The Role of Simplicity and the Emergence of Norms\*

Gabrielle Gayer<sup>†</sup> and Itzhak Gilboa<sup>‡</sup>

March 2012

## Abstract

We consider the dynamics of reasoning by general rules (theories) and specific cases (analogies). When an agent faces an exogenous process, we show that, under mild conditions, if reality happens to be simple, the agent will converge to adopt a theory and discard analogical thinking. If, however, reality is complex, the agent may rely on analogies more than on theories. By contrast, when the process is generated by agents' predictions, convergence to a theory is much more likely, as in the emergence of norms in a coordination game. Mixed cases, involving noisy endogenous processes are likely to give rise to complex dynamics of reasoning, switching between theories and analogies.

## 1 Introduction

An economic agent attempts to predict the value of a variable  $y$ . To do so, she can use certain observable variables,  $x$ , as well as the history of both  $x$  and  $y$ . How would the agent reason?

One mode of reasoning that is commonly used by economists, both for prediction and for the modeling of economic agents' predictions, is regression

analysis. This could take the form of regressing  $y$  on  $x$ , regressing  $y$  on its own past values, or some combination of these. Generally, this process is *rule-based*, and it involves a selection among theories based on observations. In philosophy, this mode of reasoning is referred to as (case-to-rule) induction, and it is based on the belief that a rule that has been valid in the past will remain valid in the future. Hume (1748) famously pointed out that this belief requires justification, thereby stating the *problem of induction*. Wittgenstein (1922) suggested that the process of induction consists in finding the simplest theory that conforms to our observations. While Goodman (1955) pointed out that the notion of simplicity is language-dependent, the basic mechanism of using unrefuted theories for prediction has remained a fundamental method of inference in science, statistics, and everyday life.<sup>1</sup>

Another, perhaps simpler mode of reasoning involves analogical thinking. In its simplest manifestation, when the variable  $x$  is ignored,  $y$  is simply predicted to be the most frequently encountered value in the past. If, however, different periods are characterized by different values of  $x$ , one may wish to rely more heavily on more similar periods,<sup>2</sup> as captured by the statistical techniques of kernel estimation (Akaike, 1954, Parzen, 1962, and see also Silverman, 1986). In artificial intelligence, this mode of reasoning has been referred to as “*case-based*” (see Schank, 1986, Riesbeck and Schank, 1989), and it has been axiomatized in Gilboa and Schmeidler (2001, 2003). Slade (1991) and Kolodner (1992) pointed out some advantages of case-based systems over rule-based systems.<sup>3</sup>

Thus, both case-based reasoning and rule-based reasoning are common in everyday life, as well as in formal statistical analysis. In the artificial intelligence literature there are attempts to combine the two modes of reasoning

---

<sup>1</sup>Solomonoff (1964) showed that, in an appropriate model, the dependence of simplicity judgments on language can be bounded.

<sup>2</sup>As suggested by Hume (1748, Section IV), “From causes which appear similar we expect similar effects.”

<sup>3</sup>Their definition of rule-based systems is, however, different from the definition we use in this paper.

in order to exploit their respective advantages (see for example Rissland and Skalak, 1989, and Domingosu, 1996). However, we are unaware of theoretical work that analyzes such combinations, especially as models of human reasoning, dealing with questions such as, when do agents tend to use analogies, and when – theories? Do they converge to one such mode of reasoning in the long run, and if so, which? Or, under which conditions will case-based reasoning be asymptotically dominant, and under which conditions should we expect long run behavior to be governed by rule-based reasoning?

In this paper we address these questions. We start with an adaptation of the model of Gilboa, Samuelson, and Schmeidler (GSS, 2010), which offers a unified framework for case-based, rule-based, and Bayesian reasoning. The focus of GSS (2010) is the robustness of Bayesian reasoning, according to which all uncertainty is a priori quantified, versus case-based and rule-based modes of reasoning, which allow for unquantified uncertainties. That paper also considers examples of dynamics between rule-based and case-based reasoning, where rules (or theories) can have different domains of applicability, such as the periods starting from a certain  $t$  onwards.

Here we limit attention to theories that make predictions at each and every period, where the prediction is about  $y$  given  $x$  (and given history).<sup>4</sup> We consider a countable set of such theories, presumably all theories that are computable, that is, that can be described by a Turing machine or a PASCAL program. We contrast these theories with case-based reasoning, and consider the long-run behavior of the relative weights of these two modes of reasoning.

The analysis turns out to critically depend on the relationship between the process that generates the variable  $y$  and the reasoning process. We distinguish between two extremes: in the first  $y$  is completely independent of the agent’s reasoning process, as is a natural phenomenon such as the weather. With an *exogenous* process of this type, we show that, under mild assumptions, rule-based reasoning will prevail if reality happens to be simple, that

---

<sup>4</sup>As  $x$  itself is not the subject of prediction, such theories are not considered “Bayesian”.

is, describable by a Turing machine. However, case-based reasoning will be dominant if reality is complex. Since there are many more complex scenarios than simple ones, one may expect that, when the process is exogenous, rule-based reasoning will wither away.

We also consider situations where  $y$  is determined by the agent's reasoning. For example, in predicting social norms, or, more generally, equilibrium selection in a coordination game, several agents are trying to guess all other agents' behavior, which depends on these agents' predictions. In the extreme example of an *endogenous* process, the variable  $y$  is simply the mode of the prediction of the agents. In this case, the equilibrium in the game corresponds to an equilibrium in prediction: a prediction that is shared by the largest number of agents becomes a self-fulfilling prophecy.

For an endogenous process we show that every scenario is possible even if all the agents reason in exactly the same way. However, mild computability assumptions suggest that case-based reasoning cannot be selected asymptotically. By contrast, rule-based reasoning is likely to be dominant in the long run, because the agents' shared prediction agrees with a certain theory that becomes the theory of choice for their predictions.

Intuitively, our results suggest that an exogenous process is unlikely to be simple, and therefore such a process will continue to refute theories one by one, until case-based reasoning remains the only viable mode of reasoning. However, when the process is endogenous, because agents have the propensity to make predictions according to simple (that is, computable) theories, such theories may indeed become true.

There are many economic phenomena involving intermediate cases, where the process  $y_t$  is determined partly by agents' predictions, and partly by exogenous factors. Speculative trade is one such example. In these cases, due to the external "noise" factors, no single theory can remain valid in the long run (unless the noise factors diminish over time). Nevertheless, when the noise factors are relatively weak, it may take a very long time for the process

to converge, and the meantime the agents' reasoning will fluctuate between rule-based and case-based reasoning. In particular, the agents' reasoning may select theories that become the equilibrium prediction for a certain period, until they are refuted, and then replaced by new theories, or by periods of case-based reasoning.

The rest of the paper is organized as follows. Section 2 describes the basic framework. It uses the framework of GSS (2010) and defines rule-based and case-based reasoning. Section 3 deals with a purely endogenous process, showing that rule-based reasoning is likely to emerge in simple states of the world, but not in complex ones. Section 4 then deals with a purely endogenous process, showing that rule-based reasoning is more likely to emerge as the asymptotic mode of reasoning than case-based reasoning. Section 5 concludes with comments on some variations of these models.

## 2 Framework

### 2.1 The unified model

We adapt the unified model of induction of GSS (2010). An agent makes predictions about the value of a variable  $y$  based on some observations  $x$ . She has a history of observations of past  $x$  and  $y$  values to rely on. We make no assumptions about independence or conditional independence of the variables across periods, or any other assumption about the data generating process.

Let the set of periods be  $\mathbb{T} \equiv \{0, 1, 2, \dots, t, \dots\}$ . At each period  $t \in \mathbb{T}$  there is a *characteristic*  $x_t \in X$  and an *outcome*  $y_t \in Y$ . The sets  $X$  and  $Y$  are finite and non-empty. The set of all *states of the world* is

$$\Omega = \{\omega : \mathbb{T} \rightarrow X \times Y\}.$$

For a state  $\omega$  and a period  $t$ , let  $\omega(t) = (\omega_X(t), \omega_Y(t))$  denote the element

of  $X \times Y$  appearing in period  $t$  given state  $\omega$ . Let

$$h_t(\omega) = (\omega(0), \dots, \omega(t-1), \omega_X(t))$$

denote the history of characteristics and outcomes in periods 0 through  $t-1$ , along with the period- $t$  characteristic, given state  $\omega$ . Let  $H_t$  denote all possible histories at period  $t$ , i.e.,  $H_t = \{h_t(\omega) \mid \omega \in \Omega\}$ . We let  $(h_t, y)$  denote the concatenation of the history  $h_t$  with the outcome  $y$ .

In each period  $t \in \mathbb{T}$ , the agent observes a history  $h_t$  and makes predictions about the period- $t$  outcome,  $\omega_Y(t) \in Y$ . A *prediction* is a ranking of subsets in  $Y$  given  $h_t$ .

Predictions are made with the help of conjectures. A conjecture is an event  $A \subset \Omega$ . A conjecture can represent a theory, an association rule, an analogy, or in general any reasoning aid one may employ in predicting  $y_t$ . Indeed, any such reasoning tool can be described extensively, by the set of states that are compatible with it. However, not every subset of  $\Omega$  may be considered by the agent. Rather, we assume that the agent only conceives of a *countable* subset  $\mathcal{A}$  of  $2^\Omega$ , referred to as the set of *conjectures*. We explain below why countability is a natural restriction for our purposes. For the time being, we mention that only countable sets are considered, so that summation over such sets will be well-defined.

GSS (2010) show that the notion of conjectures is general enough to capture Bayesian, rule-based, as well as case-based reasoning. Specifically, they assume that the agent has a *model*, which is a function  $\phi : \mathcal{A} \rightarrow \mathbb{R}_+$ , where  $\phi(A)$  is interpreted as the weight attached to conjecture  $A$  for the purpose of prediction. For a subset of conjectures  $\mathcal{D} \subset \mathcal{A}$ ,  $\phi$  is defined additively, that is,

$$\phi(\mathcal{D}) = \sum_{A \in \mathcal{D}} \phi(A).$$

It sacrifices no generality to assume that  $\phi(\mathcal{A}) = 1$ .<sup>5</sup>

---

<sup>5</sup>In GSS (2010), the set of conjectures is uncountable, and  $\phi$  is defined as a measure over

For a history  $h_t \in H_t$ , define

$$[h_t] = \{\omega \in \Omega \mid (\omega(0), \dots, \omega(t-1), \omega_X(t)) = h_t\}.$$

Thus,  $[h_t]$  is the event consisting of all states that are compatible with the history  $h_t$ . Similarly, for  $h_t \in H_t$  and a subset of outcomes  $Y' \subset Y$ , we define the event

$$[h_t, Y'] = \{\omega \in [h_t] \mid \omega_Y(t) \subset Y'\},$$

consisting of all states that are compatible with the history  $h_t$  and with the next outcome being in the set  $Y'$ .

The agent learns by ruling out conjectures that have been refuted by evidence. Specifically, given a history  $h_t \in H_t$ , a conjecture  $A$  that is disjoint from  $[h_t]$  should not be taken into consideration in future predictions. Fixing a subset of conjectures  $\mathcal{D} \subset \mathcal{A}$ , a history  $h_t \in H_t$  and a subset of outcomes  $Y' \subset Y$ , consider the set of conjectures in  $\mathcal{D}$  that have not been refuted by  $h_t$  and that predict the outcome will be in  $Y'$ :

$$\mathcal{D}(h_t, Y') = \{A \in \mathcal{D} \mid \emptyset \neq A \cap [h_t] \subset [h_t, Y']\}.$$

Observe that the conjectures in  $\mathcal{D}(h_t, Y')$  are various events, many pairs of which may not be disjoint. This is important to bear in mind in the following definitions, where we sum over the weights assigned to different conjectures.

Given a model  $\phi : \mathcal{A} \rightarrow \mathbb{R}_+$ , the weight assigned to  $Y'$  by the unrefuted conjectures in  $\mathcal{D}$  is

$$\phi(\mathcal{D}(h_t, Y')).$$

The total weight assigned to a subset  $Y' \subset Y$  by all unrefuted conjectures is thus given by

$$\phi(\mathcal{A}(h_t, Y')).$$

---

subsets of conjectures, that is, subsets of subsets of states of the world. This complication is obviated thanks to the countability assumption.

The agent’s prediction is a ranking of the subsets of  $Y$ , with  $Y'$  considered more likely than  $Y''$  iff

$$\phi(\mathcal{A}(h_t, Y')) > \phi(\mathcal{A}(h_t, Y'')).$$

It will be useful to have notation for the set of conjectures, in a class  $\mathcal{D} \subset \mathcal{A}$ , that are relevant for prediction at history  $h_t$ :

$$\mathcal{D}(h_t) = \cup_{Y' \subseteq Y} \mathcal{D}(h_t, Y')$$

Observe that  $\mathcal{D}(h_t)$  is the set of conjectures in  $\mathcal{D}$  that have not been refuted and that could lend their weight to *some* nontautological prediction after history  $h_t$  (and hence  $\mathcal{D}(h_t) \subset \mathcal{D}(h_t, Y)$ .)

## 2.2 Rule-based reasoning: theories

The notion of a rule is rather general. There are *association rules*, which, conditional on the value of  $x_t$ , restrict the possible values of  $y_t$ . For example, the rule “if the Democratic candidate wins the election, taxes will rise” says something about the rate of taxation,  $y_t$  if the president is a Democrat (i.e., if  $x_t$  assumes a certain value). Such a rule does not restrict prediction in case its antecedent does not hold. By contrast, there are *functional rules*, which predict that  $y_t$  be equal to  $f(x_t)$  for a certain function  $f$ . Other rules may be time-dependent, and allow  $y_t$  to be a function of  $x_t$  as well as of  $t$  itself. Further, rules may differ in their domain. In particular, GSS (2010) provide an example of rule-based reasoning in which the rules predict a certain constant  $y$  value beginning with a given period  $t$ , and making no predictions prior to that  $t$ .

In this paper we restrict attention to rules that can be viewed as general theories. Such theories are constrained to make a specific prediction (i.e., a single  $y_t$ ) at each and every  $t$ , and for any possible value of  $x_t$ . Moreover, we will allow such functions to depend on the entire history  $h_t$ , and thus on previous values  $(x_i, y_i)$  for  $i < t$ . However, we make one important assumption:

all the functions we consider are computable by Turing machines. That is, we consider only those theories  $f : \cup_{t \geq 0} H_t \rightarrow Y$  for which there exists a Turing machine (or, equivalently, a PASCAL program), which, for every  $t$  and every  $h_t$ , halts in finite time. This appears to be a minimal requirement because a theory that does not halt will fail to compute the value  $y_t = f(h_t) \in Y$  for every  $t$ . It is well known that there are only countably many such theories. We denote the set of *theories* by  $\mathcal{R} = \{f_1, f_2, \dots\}$ .

Observe that the definition assumes that a theory  $f_j \in \mathcal{R}$  computes a prediction for every history  $h_t$ , including histories that are inconsistent with  $f_j$  itself. This is reminiscent of the definition of a strategy in extensive form games. Alternatively, one may restrict the domain of a theory  $f$  only to the histories that do not contradict it.<sup>6</sup>

One may wish to enrich the model by introducing Turing machines (or computer programs) explicitly. In this case, each theory  $f$  will be represented by infinitely many machines, which are observationally equivalent. The agent will not be able, in general, to tell which machines are equivalent, but equivalent machines will be refuted at the same histories, and thus their impact on predictions will be the same as that of the function  $f$  they represent.

To avoid problems related with undecidability,<sup>7</sup> one may restrict attention to a subset of theories that can be proved to always halt. As long as the subset considered is sufficiently rich to be able to describe any finite history, our results will hold.

If there are no  $x$  values to be observed (that is,  $|X| = 1$ ), then for every  $f_j \in \mathcal{R}$ , there exists a unique state of the world compatible with it. In this case, a model  $\phi$  that puts positive weight only on theories in  $\mathcal{R}$  can also be

---

<sup>6</sup>Such a restriction would make no major difference, because the definition of a theory at histories incompatible with it will be immaterial for our purposes. Clearly, a computable theory that is defined on the restricted domain can be extended to a computable theory on the entire domain, say, by predicting a constant  $y$  for all histories that are incompatible with the theory.

<sup>7</sup>This is known as the "Halting Problem" by which there is no general method to determine whether a program will halt in finite time.

viewed as a Bayesian model (as defined in GSS, 2010), namely as a model assigning probabilities to single states.<sup>8</sup> However, in the more general case, a theory  $f_j \in \mathcal{R}$  is compatible with a non-singleton conjecture, because such a theory, as opposed to a Bayesian conjecture, need not predict the values of the  $x_t$ 's.

For a model  $\phi$  and a theory  $f_j \in \mathcal{R}$ , we will use  $\phi(f_j)$  to denote the weight assigned by  $\phi$  to the conjecture consisting of all the states that do not contradict  $f_j$ , that is,  $\phi(f_j) = \phi([f_j])$  where

$$[f_j] = \{\omega \in \Omega \mid \omega_Y(t) = f_j(h_t) \quad \forall t\}.$$

A model  $\phi_R$  is *purely rule-based* if  $\phi_R(\mathcal{R}) = 1$ , equivalently,  $\phi_R(\mathcal{A} \setminus \mathcal{R}) = 0$  or  $\sum_j \phi_R(f_j) = 1$ . Such a model can also be viewed as a probability distribution over  $\mathcal{R}$ .

### 2.3 Case-based reasoning: analogies

Case-based conjectures are defined as in GSS (2010): for every  $i < t$ ,  $x, z \in X$ , let

$$A_{i,t,x,z} = \{\omega \in \Omega \mid \omega_X(i) = x, \omega_X(t) = z, \omega_Y(i) = \omega_Y(t)\}.$$

We can interpret this conjecture as indicating that, *if* the input data in period  $i$  are given by  $x$  and in period  $t$  – by  $z$ , *then* periods  $i$  and  $t$  will produce the same outcome (value of  $y$ ). Notice that a single case-based conjecture consists of many states:  $A_{i,t,x,z}$  does not restrict the values of  $\omega_X(k)$  or  $\omega_Y(k)$  for  $k \neq i, t$ .

Let the set of all conjectures of this type be denoted by

$$\mathcal{CB} = \{A_{i,t,x,z} \mid i < t, x, z \in X\} \subset \mathcal{A}. \quad (1)$$

A model  $\phi_{CB}$  is *purely rule-based* if  $\phi_{CB}(\mathcal{CB}) = 1$ . Such a model can also be viewed as a probability distribution over  $\mathcal{CB}$ .

---

<sup>8</sup>The resulting Bayesian prior, however, is restricted to have a countable support consisting of computable states.

For example, the agent might have a similarity function over the characteristics,

$$s : X \times X \rightarrow \mathbb{R}_+,$$

and a memory decay factor  $\beta \leq 1$ . Given history  $h_t = h_t(\omega) \in H_t$ , a possible outcome  $y \in Y$  is assigned a weight proportional to

$$S(h_t, y) = \sum_{i=0}^{t-1} \beta^{t-i} s(\omega_X(i), \omega_X(t)) \mathbf{1}_{\{\omega_Y(i)=y\}},$$

where  $\mathbf{1}$  is the indicator function of the subscripted event. Hence, the agent may be described as if she considered past cases in the history  $h_t$ , chose all those that resulted in some period  $i$  with the outcome  $y$ , and added to the sum  $S(h_t, y)$  the similarity of the respective characteristic  $\omega_X(i)$  to the current characteristic  $\omega_X(t)$ . The resulting sums  $S(h_t, y)$  can then be used to rank the possible outcomes  $y$ . If  $\beta = 1$  and in addition the similarity function is constant, the resulting number  $S(h_t, y)$  is proportional to the relative empirical frequency of  $y$ 's in the history  $h_t$ .

As noted by GSS (2010), for every similarity function  $s$  and decay factor  $\beta$  one may define a model  $\phi_{s,\beta}$  by setting  $\phi_{s,\beta}(A_{i,t,x,z})$ , for each  $t$ , to be proportional to  $\beta^{(t-i)}s(x, z)$ , and  $\phi_{s,\beta}(\mathcal{A} \setminus \mathcal{CB}) = 0$ . In this case, for every history  $h_t$  and every  $y \in Y$ ,  $\phi_{s,\beta}(\mathcal{A}(h_t, \{y\}))$  is proportional to  $S(h_t, y)$ . Such a model  $\phi_{s,\beta}$  will be equivalent to case-based prediction according to the function  $S$ .

## 2.4 Open-Mindedness

We restrict our agent to a specific type of rule-based reasoning and a similarly specific type of case-based reasoning. Formally, we assume that the set of conjectures is  $\mathcal{A} = \mathcal{R} \cup \mathcal{CB}$ . Within this constraint, we wish to guarantee that the agent is open-minded. Thus, we will henceforth assume that the agent assigns a positive weight  $\phi(A) > 0$  to each conjecture in  $\mathcal{A} = \mathcal{R} \cup \mathcal{CB}$ . We denote this set of *open-minded* models by  $\Phi_+$ .

### 3 Exogenous Process

#### 3.1 Simplicity Result

For each theory  $f_j \in \mathcal{R}$ , recall that  $[f_j]$  is the event in which  $f_j$  is never refuted. All states  $\omega \in [f_j]$  are simple in a certain sense: the computation of  $y_t$  given  $h_t$  can be done in a finite time, employing a program that is independent of  $t$ . Observe that the pattern of  $x_t$ 's in  $\omega$  may be rather complicated, and, in particular, it can be a pattern that cannot be computed by any Turing machine. However, since the agent's task is to predict  $y_t$  given  $h_t$ , we ignore this complexity. We therefore define the *set of simple states* to be

$$\mathbb{S} = \bigcup_{r \geq 1} [f_r]$$

(or  $\mathbb{S} = \bigcup_{f \in \mathcal{R}} [f]$ ).

We can now state

**Proposition 1** *For every  $\phi \in \Phi_+$  and every  $\omega \in \mathbb{S}$ ,*

$$\frac{\phi(\mathcal{CB}(h_t(\omega)))}{\phi(\mathcal{R}(h_t(\omega)))} \rightarrow 0$$

as  $t \rightarrow \infty$ .

That is, in all simple states, the agent will converge to reason by theories and will gradually discard case-based reasoning.

The logic of this proposition is straightforward: if we consider a simple state  $\omega$ , where a certain simple theory  $f_r$  holds, the initial weight assigned to this theory will serve as a lower bound on  $\phi(\mathcal{R}(h_t(\omega)))$  for all  $t$ , because the theory will never be refuted at  $\omega$ . By contrast, the total weight of the set of all case-based conjectures that are relevant for prediction at time  $t$  converges to zero because it is an element in a convergent series. Intuitively, because at  $\omega$  the theory  $f_r$  is correct, it retains its original weight of credence. By contrast, case-based conjectures concern only pairs of periods,  $i < t$ , and

thus, for each new value of  $t$ , a new set of case-based conjectures is being considered. It is inevitable that the total weight of this set (which is disjoint from sets considered in previous periods) converge to zero.

### 3.2 The Fragility of Rule-Based Reasoning

We start by observing that, in most states of the world, the weight put on rule-based reasoning has to decay exponentially fast. To capture the notion of “most” states of the world, we introduce a measure over  $\Omega$ . Endow the state space  $\Omega$  with the  $\sigma$ -algebra  $\Sigma$  defined by the variables  $(x_t, y_t)_{t \geq 0}$ . A probability measure  $\lambda$  on  $\Sigma$  is a *non-trivial conditionally iid measure* if, for every  $x \in X$  there exists  $\lambda_x \in \Delta(Y)$  such that (i) for every  $h_t = ((x_0, y_0), \dots, (x_{t-1}, y_{t-1}), x_t)$ , the conditional distribution of  $Y$  given  $h_t$  according to  $\lambda$  is  $\lambda_x$ ; and (ii)  $\lambda_x$  is non-degenerate for every  $x \in X$ . The measure  $\lambda$  is assumed neither to govern the actual process, nor to capture the reasoner’s beliefs. It is merely a way to quantify states of the world, and capture the intuition that certain events are small relative to others.

**Proposition 2** *Let there be given  $\phi \in \Phi_+$  and let  $\lambda$  be a non-trivial conditionally iid measure. For every  $\varepsilon > 0$  there exists  $T_0$  such that*

$$\lambda \left( \left\{ \omega \mid \phi(\mathcal{R}(h_t(\omega))) \leq \delta^{t/2} \quad \forall t \geq T_0 \right\} \right) > 1 - \varepsilon.$$

This result states that, apart from a  $\lambda$ -negligible event, the weight of the rule-based conjectures decreases at a semi-exponential rate. Clearly, this cannot be the case in the simple state, where the weight of the rule-based conjectures remains bounded away from zero. But there are only countably many simple states, and they are therefore of  $\lambda$ -measure zero. Thus, there can be many non-simple states at which the weight of the rule-based conjectures does not decay very fast, but the total ( $\lambda$ -)weight of all these states, simple or non-simple, is negligible.

Does the fast decay of the weight of the rule-based conjectures mean that the reasoner will tend to use more case-based conjectures? The answer

depends on the rate at which the weight of the case-based conjectures tends to zero. Thus, we are led to ask, how are the weights to be spread over the case-based conjectures?

One may argue that it is intuitive for the total weight of the case-based conjectures at a given time to be independent of  $t$ . However, the set of case-based conjectures that are relevant at  $t$  is disjoint from the corresponding set for  $t' \neq t$ . It is therefore a mathematical necessity that the weight assigned to all case-based conjectures relevant at period  $t$  converge to zero (as in the proof of Proposition 1). However, there is no reason for this total weight to converge to zero too fast. We therefore assume that the weight of all case-based conjectures, across all periods, is split among them so that the case-based conjectures relevant for prediction at each history  $h_t$  command a positive weight that does not diminish too fast as a function of  $t$ . This will be the case if, for instance, the total weight is split proportionately to a strictly positive similarity matrix  $S : X^2 \rightarrow \mathbb{R}$ .

Formally, define  $\Phi_+^p \subset \Phi_+$  to be the set of models  $\phi$  for which there exist  $\gamma < -1$  and  $c > 0$ , such that, for every  $t$ , and every  $x, z \in X$ ,

$$\sum_{i < t} \phi(A_{i,t,x,z}) \geq ct^\gamma$$

Under these assumptions, the opposite of that of Proposition 1 holds almost everywhere:

**Proposition 3** *Let there be given a model  $\phi \in \Phi_+^p$  and a non-trivial conditionally iid measure  $\lambda$ . Then,  $\lambda$ -almost everywhere,*

$$\frac{\phi(\mathcal{R}(h_t(\omega)))}{\phi(\mathcal{CB}(h_t(\omega)))} \rightarrow 0$$

as  $t \rightarrow \infty$ .

## 4 Endogenous Process

In this section we consider a process that is governed by the reasoning of a set of agents. For example, consider the behavior of agents involved in a coordination game, where each agent tries to predict the social norm that will govern the behavior of others, and to match that norm in her choice of strategy.

In this section we analyze the case in which all agents share the same weight function  $\phi \in \Phi$ . Beyond serving as an important benchmark, this extreme case attempts to capture the intuition that, while people vary in their a priori judgment of theories, these judgments are correlated. Specifically, people tend to prefer simpler theories to more complex ones, and similarity judgments are correlated across people. For example, people might disagree whether the pattern 011111... is simpler than the pattern 010101..., but practically everyone would agree that 000000... is simpler than 011001... (where readers might wonder how the last sequence is meant to be continued). For such a function  $\phi$  define

$$\Omega_\phi = \left\{ \omega \in \Omega \mid \omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{A}(h_t, \{y\})) \quad \forall t \geq 0 \right\}.$$

Thus, it is assumed that the agents' predictions determine the actual outcome. As in the case of the exogenous process, the agents are not assumed to predict the values of  $x_t$ , nor to affect them.

We first note that every state of the world may unfold in an endogenous process:

**Proposition 4** *For every  $\omega \in \Omega$ , there exists  $\phi \in \Phi_+^p$  such that  $\omega \in \Omega_\phi$ .*

The proof of Proposition 4 is constructive: given a state  $\omega \in \Omega$  the proof describes an algorithm that generates  $\phi \in \Phi_+^p$  such that  $\omega \in \Omega_\phi$ . However, if the state  $\omega$  itself is not computable, the resulting  $\phi$  may also not be computable. Hence the message of the proposition should be qualified:

while every state may materialize as the prediction of the agents, if we make the plausible assumption that the agents can only make predictions using a computable  $\phi$ , not all states are necessarily possible.

We therefore restrict attention to models  $\phi$  that are computable functions assuming rational values. That is, consider only the set of functions  $\Phi_+^{cp} \subset \Phi_+^p$  such that, for each  $\phi \in \Phi_+^{cp}$ , there is a machine that computes  $\phi(A) \in \mathbb{Q}$  for each conjecture  $A$ . This assumption allows us to imagine the agent as actually trying to compute  $\phi(A(h_t, \{y\}))$  for each  $y \in Y$ , and choosing an  $\varepsilon$ -maximizer of  $\phi(A(h_t, \{\cdot\}))$  as her prediction.<sup>9</sup> Clearly, this interpretation is not the only one, and one may think of the computation of  $\phi(\mathcal{A}(h_t, Y'))$  as a model that an outsider observer uses in order to provide a description of the agent's predictions.

Our interest is in the dynamics of reasoning of the agents along states in  $\Omega_\phi$  for  $\phi \in \Phi_+^{cp}$ . To this end, we introduce the following definitions. *Rule-based reasoning is dominant* at state  $\omega \in \Omega_\phi$  at period  $t$  if

$$(i) \quad \phi(\mathcal{R}(h_t(\omega))) > \phi(\mathcal{CB}(h_t(\omega)))$$

*and*

$$(ii) \quad \omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{R}(h_t, \{y\})).$$

Thus, rule-based reasoning is dominant if there is more weight on rule-based reasoning than on case-based reasoning, and if the prediction of the rule based reasoning is indeed the prediction that the agents make (and that defines the next observation  $y_t$ ). Similarly, we say that *case-based reasoning is dominant*

---

<sup>9</sup>Observe that the computation of  $\phi(A(h_t, \{y\}))$  involves infinite summations. Hence the agent cannot simply compute  $\phi(A(h_t, \{y\}))$  for each  $y$  with perfect precision. However, the agent can be imagined to simultaneously approximate these values and halt the computation if the difference between the values is larger than the residual weight, or if the residual weight is below a certain threshold. This would result in a computable procedure that approximates the maximization  $\phi$  of in the sense that it provides an  $\varepsilon$ -maximization of  $\phi$

at state  $\omega \in \Omega_\phi$  at period  $t$  if

$$(i) \quad \phi(\mathcal{R}(h_t(\omega))) < \phi(\mathcal{CB}(h_t(\omega)))$$

and

$$(ii) \quad \omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{CB}(h_t, \{y\})).$$

Observe that, at  $\omega \in \Omega_\phi$  at period  $t$  we may have neither mode of reasoning dominating either if they happen to be equally weighty, that is, if,  $\phi(\mathcal{R}(h_t(\omega))) = \phi(\mathcal{CB}(h_t(\omega)))$ , or if the weightier mode of reasoning does not correctly predict the outcome. This may happen, for instance, if the conjectures in the dominant mode of reasoning split the weight between the different predictions, so as to make the other mode of reasoning pivotal.

For  $\phi \in \Phi_+^{cp}$  we are interested in the long-run existence of a dominant mode of reasoning. Define  $\Omega_{RB\phi}$  to be the set of states  $\omega \in \Omega_\phi$  such that, for some  $T$ , rule-based reasoning is dominant at state  $\omega \in \Omega_\phi$  at all  $t \geq T$ . Define  $\Omega_{CB\phi}$  accordingly to be the states at which case-based reasoning dominates from some period on.

**Proposition 5** *For every  $\phi \in \Phi_+^{cp}$  we have  $\mathbb{S} \subset \Omega_{RB\phi}$ .*

Thus, for every weight function that satisfies our assumptions, the set of states in which rule-based reasoning is eventually dominant contains all the simple states. One might wonder whether in complex states case-based reasoning might be dominant in the long run. The negative answer is given by

**Proposition 6** *For every  $\phi \in \Phi_+^{cp}$  we have  $\Omega_{CB\phi} = \emptyset$ .*

The reasoning behind Proposition 6 is very simple: if  $\omega$  were a state that is, in the long run, governed by case-based reasoning, then, because  $\phi$  is computable, there exists a theory that simulates the case-based reasoning defined by  $\phi$ . For example, if all agents simply use the modal  $y$  for prediction, there

exists a simple algorithm that describes their prediction, and therefore the resulting state  $\omega$ . Since an open-minded  $\phi$  must have assigned this algorithm a positive weight a priori, the theory described by this algorithm will eventually prevail as the correct theory used for prediction.

By the same logic, one might be tempted to suggest that, for any computable  $\phi$ ,  $\Omega_{RB\phi} = \Omega_\phi$ , that is, that the process ends up in a rule-based state. This conclusion would not be warranted for two reasons: (i) the condition  $\omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{A}(h_t, \{y\}))$  does not require that  $\omega_Y(t)$  be a single maximizer of  $\phi(\mathcal{A}(h_t, \{y\}))$ ; in case of ties,  $\omega$  may involve a pattern of choices of  $y$  that is not computable; and, moreover, (ii) as mentioned above, computability of  $\phi$  does not imply that  $\phi(\mathcal{A}(h_t, \{y\}))$  is computable, as the latter involves an infinite summation. (This cannot happen when one restricts attention to case-based conjectures, but it will necessarily be the case when rule-based conjectures are concerned.)

## 5 Variants

### 5.1 Hybrid models

Consider the case of trade in financial markets. Financial assets are affected by various economic variables that are exogenous to the market, ranging from weather conditions to technological innovation, from demand shocks to political revolutions. At the same time, financial assets are worth what the market “thinks” they are worth. In other words, such markets have a strong endogenous factor as well. It seems natural to assume that such processes ( $y_t$ ) are governed partly by the predictions ( $\hat{y}_t$ ) as in Section 4 and partly by random shocks as in Section 3. For instance, assume that  $\alpha(h_t)$  is the probability that agents’ reasoning determines  $y_t$ , and with the complement probability  $y_t$  is determined by a random shock. That is,

$$y_t = \begin{cases} \hat{y}_t & \alpha(h_t) \\ \tilde{y}_t & 1 - \alpha(h_t) \end{cases}$$

where  $\hat{y}_t \in \arg \max_{y \in Y} \phi(\mathcal{A}(h_t, \{y\}))$  and  $\tilde{y}_t$  is uniformly distributed over  $Y$ . Thus, if  $\alpha(h_t) \equiv 1$  we consider a model as in Section 4, which is likely to converge to a single dominant theory, and when  $\alpha(h_t) \equiv 0$  we consider a model as in Section 3, coupled with a non-degenerate iid measure that guarantees asymptotic case-based reasoning. Obviously, the interesting case is where  $\alpha(h_t) \in (0, 1)$  (for most if not all histories  $h_t$ ).

If  $\alpha(h_t)$  is independent of history, so that  $\alpha(h_t) \equiv \alpha \in (0, 1)$ , no theory can be dominant asymptotically. Indeed, every theory that correctly predicts  $\hat{y}_t$  has a fixed positive probability  $(1 - \alpha)$  of being refuted at each period, and will thus be refuted at some point with probability 1. Moreover, when  $t$  is large, we know that with very high probability the number of “noise” periods is approximately  $(1 - \alpha)t$ . Over these periods we are likely to observe a complex pattern of  $y_t$ ’s, and thus a result similar to Proposition 3 holds: the total weight of rule-based conjectures decreases, on average, exponentially fast in the number of noise periods. Because the number of noise periods increases linearly in  $t$  (as it is roughly  $(1 - \alpha)t$ ), this weight is also an exponentially decreasing function of  $t$  and thus it decays faster than do the case-based conjectures. Thus, case-based reasoning will be asymptotically dominant in “most” states of the world even if  $\alpha(h_t) \equiv \alpha$  is very close to 1.

However, the probability of noise in an endogenous process is likely to be endogenous as well. For example, consider the choice of driving on the right or on the left in a large population. When agents are not quite sure which equilibrium is being played, it is easier for a random shock to switch equilibria. But when all the agents are rather certain that everyone is going to drive, say, on the right, it is highly unlikely that at least half of them would behave differently that they would find optimal based on their predictions. Thus, it stands to reason that  $\alpha(h_t)$  depends on  $h_t$ , and, moreover, that it converges to 1 as  $t$  grows, if a simple theory fits the data  $h_t$ . Such convergence would allow the process to be asymptotically dominated by rule-based conjectures with positive probability.

## 5.2 Heterogenous beliefs

The analysis in Section 4 assumes that all agents share the function  $\phi$ , which is the natural counterpart of the common prior assumption in economics. Clearly, this assumption is not entirely realistic; people vary in their similarity judgments, in their prior beliefs in theories, as well as in their tendency to reason by theories vs. by analogies. Hence one may consider an endogenous process in which the population is distributed among different credence functions  $\phi$ .

Importantly, the distinction between computable and incomputable states is an objective one. Agents may vary in the language they use to describe theories, and, correspondingly, in their judgment of simplicity. However, any two languages that are equivalent to the computational model of a Turing machine can be translated to each other. Thus, if the process follows a simple (computable) path, all agents will notice this regularity. Different agents may discard case-based reasoning in favor of the unrefuted theory at different times, but (under the assumption of open-mindedness) all of them will eventually realize that this unrefuted theory is indeed “correct”. Interesting dynamics might emerge if the agents who are slow to switch to prediction by the correct theory are sufficiently numerous to refute that theory, thereby changing the reasoning of those agents who were the first to adopt the theory.

## 6 Appendix: Proofs

### 6.1 Proof of Proposition 1

Assume that  $\omega \in [f_r]$  for some  $r$ . In this case the denominator is bounded from below by the weight assigned to the correct theory  $f_r$ . In fact,

$$\mathcal{R}(h_t(\omega)) \searrow \phi(f_r) > 0$$

as  $t \rightarrow \infty$ .

By contrast,  $\mathcal{CB}(h_t(\omega))$  includes the  $\phi$ -weight only of those case-based conjectures that are relevant at  $t$ , that is

$$\phi(\mathcal{CB}(h_t(\omega))) = \sum_{\{(i,x,z)|i < t, \omega_X(i)=x, \omega_X(t)=z\}} \phi(A_{i,t,x,z})$$

Clearly,

$$\phi(\mathcal{CB}(h_t(\omega))) \leq \sum_{\{(i,x,z)|i < t\}} \phi(A_{i,t,x,z})$$

Defining

$$\alpha_t = \sum_{\{(i,x,z)|i < t\}} \phi(A_{i,t,x,z})$$

and observing that

$$\sum_t \alpha_t = \phi(\mathcal{CB}) < 1$$

we must have

$$\alpha_t \rightarrow 0$$

as  $t \rightarrow \infty$ . Hence  $\phi(\mathcal{CB}(h_t(\omega)))$  also converges to zero as  $t \rightarrow \infty$ , and this completes the proof.

### 6.2 Proof of Proposition 2

Let there be given an open-minded model  $\phi$ . For a period  $t$  and a sequence  $x_{(t)} = (x_0, \dots, x_{t-1}) \in X^t$ , consider the state space  $\Omega_{x_{(t)}}$  defined by the corresponding  $y_{(t)} = (y_0, \dots, y_{t-1}) \in Y^t$  and containing  $|Y|^t$  states. Thus  $\Omega_{x_{(t)}}$  is a

replica of  $Y^t$  and when no confusion is likely to arise we will refer to elements of  $\Omega_{x(t)}$  as  $y(t)$ .

Let  $\delta < 1$  be such that  $\lambda_0((x, y)) < \delta$  for every  $(x, y) \in X \times Y$ . Observe that  $\lambda$  attaches a probability not exceeding  $\delta^t$  to each element in the space  $\Omega_{x(t)}$ .

Let  $W$  be a random variable defined on  $\Omega_{x(t)}$ , and measuring the total weight of rule-based conjectures that are compatible with history. That is, for  $y(t) = (y_0, \dots, y_{t-1})$  choose an arbitrary  $x_t \in X$  and define  $h_t$  by  $h_t = ((x_0, y_0), \dots, (x_{t-1}, y_{t-1}), x_t)$ . Choose  $\omega$  such that  $h_t(\omega) = h_t$  and define

$$W(y(t)) = \phi(\mathcal{R}(h_t(\omega)))$$

Clearly, such states  $\omega$  exist. Importantly,  $\mathcal{R}(h_t(\omega))$  does not depend on the choice of  $x_t$  because theories are not required to predict  $x_t$  and therefore no observation of  $x_t$  will rule out any theories. It is also obvious that the choice of  $\omega$  such that  $h_t(\omega) = h_t$  does not affect  $\mathcal{R}(h_t(\omega))$ , because yet-unobserved variables do not rule out theories.

Observe that  $\{\mathcal{R}(h_t(\omega))\}_\omega$  defines a partition of  $\mathcal{R}$ : each theory  $f \in \mathcal{R}$  is compatible with precisely one state  $y(t) \in \Omega_{x(t)}$ . Hence

$$\sum_{y(t) \in \Omega_{x(t)}} \phi(\mathcal{R}(h_t(\omega))) = r < 1$$

and therefore

$$\begin{aligned} E(W) &= \sum_{y(t) \in \Omega_{x(t)}} \lambda_{|x(t)}(y(t)) W(y(t)) \\ &= \sum_{y(t) \in \Omega_{x(t)}} \lambda_{|x(t)}(y(t)) \phi(\mathcal{R}(h_t(\omega))) \\ &< \delta^t r < \delta^t. \end{aligned}$$

Denoting by  $B_t$  the event  $W > \delta^{t/2}$ , and using Markov's inequality, we get

$$\lambda_{|x(t)}(B_t) = \lambda_{|x(t)}(W > \delta^{t/2}) < \frac{E(W)}{\delta^{t/2}} < \frac{\delta^t}{\delta^{t/2}} = \delta^{t/2}.$$

We will also use  $B_t$  to denote the corresponding event in  $\Omega$ . Since we have shown that  $\lambda_{|x(t)}(B_t) = \lambda(B_t|x(t)) < \delta^{t/2}$  for all  $x(t)$ , we also have  $\lambda(B_t) < \delta^{t/2}$ .

Next observe that the bounds on the probabilities of the various  $B_t$  events converge. In fact,

$$\sum_{t \geq T} \delta^{t/2} \leq \sum_{t \geq 0} \delta^{t/2} = \frac{1}{1 - \sqrt{\delta}}.$$

This implies that for the given  $\varepsilon > 0$  there is a large enough  $T_0$  such that

$$\sum_{t \geq T_0} \delta^{t/2} < \varepsilon$$

and thus, for this  $T_0$ ,

$$\lambda(\cup_{t \geq T_0} B_t) < \varepsilon$$

and

$$\lambda\left(\left\{\omega \mid \phi(\mathcal{R}(h_t(\omega))) \leq \delta^{t/2} \quad \forall t \geq T_0\right\}\right) > 1 - \varepsilon.$$

### 6.3 Proof of Proposition 3

Consider a given  $\varepsilon > 0$  and let  $T_0$  be the period provided by Proposition 2. Then, on the corresponding event (whose probability is at least  $1 - \varepsilon$ )

$$\phi(\mathcal{R}(h_t(\omega))) \leq \delta^{t/2} \quad \forall t \geq T_0$$

and this, together with the assumption that  $\phi \in \Phi_+^p$ , that is,  $\sum_{i < t} \phi(A_{i,t,x,z}) \geq ct^\gamma$  for  $c > 0$  and  $\gamma < -1$ , implies that

$$\frac{\phi(\mathcal{R}(h_t(\omega)))}{\phi(\mathcal{CB}(h_t(\omega)))} < \frac{\delta^{t/2}}{ct^\gamma}$$

where the right hand side converges to 0 as  $t$  tends to  $\infty$ .

Considering a sequence  $\varepsilon_n \searrow 0$ , one concludes that the convergence to 0 occurs everywhere apart from a set whose  $\lambda$ -measure is zero.

## 6.4 Proof of Proposition 4

Let there be given  $\omega \in \Omega$ . For simplicity of notation, we define  $\phi$  without guaranteeing the normalization  $\phi(\mathcal{A}) = 1$ . It will be obvious from the construction, however, that  $0 < \phi(\mathcal{A}) < \infty$  so that  $\phi$  can be normalized.

We first define  $\phi$  on the case-based conjectures. For every  $t \geq 1$ , let

$$\phi(A_{i,t,x,z}) = \frac{1}{(t+5)^3}.$$

(We use a “lag” of 5 periods to make sure that the rate of decay between any two consecutive periods is not too fast. Specifically, we wish to guarantee that each element in the sequence is at least half of its predecessor.)

Clearly,

$$\phi(\mathcal{CB}) \leq |X|^2 \sum_{t \geq 1} \left[ t \frac{1}{(t+5)^3} \right] < \infty.$$

We now turn to define  $\phi$  on  $\mathcal{R}$ . In the proof we wish to assign weights to subsets of conjectures in  $\mathcal{R}$ . Note that for every subset  $\mathcal{R}' \subset \mathcal{R}$  and every  $a > 0$  one may assign a positive weight  $\phi(f) > 0$  to each  $f \in \mathcal{R}$  such that  $\phi(\mathcal{R}') = a$ , say by considering an enumeration of  $\mathcal{R}'$ ,  $f_1, f_2, \dots$  and setting  $\phi(f_j) = a/2^j$ . In the rest of this proof, we will simply say “assign a weight  $a > 0$  to the subset  $\mathcal{R}'$ ”, referring to such an assignment.

If  $\omega \in \mathbb{S}$ , there exists a theory  $f \in \mathcal{R}$  such that  $\omega \in [f]$ . In this case, assign  $\phi(f) = 1$  and assign the weight  $a = 1/4$  to the set of all the other theories,  $\mathcal{R} \setminus \{f\}$ . It is easily observed that, at each  $t \geq 0$ ,  $\omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{A}(h_t, \{y\}))$  and thus  $\omega \in \Omega_\phi$  is established, while  $\phi \in \Phi_+^p$  holds.

Next assume that  $\omega \notin \mathbb{S}$ . Denote, for  $t \geq 0$ ,

$$\mathcal{R}_t = \mathcal{R}(h_t(\omega)).$$

$\mathcal{R}_t$  denotes the set of theories that are unrefuted by history  $h_t(\omega)$ . Observe that they are all relevant for prediction at period  $t$ . Clearly,  $\mathcal{R}_0 = \mathcal{R}$ , as  $h_0(\omega)$  contains only the value of  $x_0$  and no theory makes any prediction

about the  $x$ 's. Moreover,  $\mathcal{R}_{t+1} \subset \mathcal{R}_t$ , because any theory that agrees with  $\omega$  for the first  $(t+1)$  observations also agrees with it for the first  $t$  observations. Finally,

$$\cap_t \mathcal{R}_t = \emptyset$$

because  $\omega \notin \mathbb{S}$ . We can thus define, for  $t > 1$ , the set of theories that are proven wrong at period  $t$  to be

$$\mathcal{W}_t = \mathcal{R}_{t-1} \setminus \mathcal{R}_t.$$

Observe that

$$\mathcal{R} = \cup_t \mathcal{W}_t$$

and

$$\mathcal{W}_t \cap \mathcal{W}_{t'} = \emptyset$$

whenever  $t \neq t'$ .

Thus, at period  $t$   $\mathcal{R}_t$  consists of all theories that were unrefuted by  $h_t(\omega)$ , and it is the disjoint union of  $\mathcal{R}_{t+1}$ , namely the theories that correctly predict  $y_t = \omega_Y(t)$  and  $\mathcal{W}_{t+1}$ , namely the theories that predict different values for  $y_t$ , and that will be proven wrong.

If we ignore the case-based conjectures, the prediction made by the theories in  $\mathcal{R}_t$  is guaranteed to be the “correct” prediction  $\omega_Y(t)$  if

$$\phi(\mathcal{R}_{t+1}) > \phi(\mathcal{W}_{t+1}).$$

(Observe that, as compared to  $h_t(\omega)$ ,  $h_{t+1}(\omega)$  specifies two additional pieces of information: the realization of  $y_t$ ,  $\omega_Y(t)$ , and the realization of  $x_{t+1}$ ,  $\omega_X(t+1)$ . However, theories do not predict the  $x$  values, and thus the theories in  $\mathcal{R}_{t+1}$  are all those that were in  $\mathcal{R}_t$  and that predicted  $y_t = \omega_Y(t)$ ; the observation of  $x_{t+1}$  does not refute any additional theories.)

A simple way to construct  $\phi \in \Phi_+^p$  is to make sure that the prediction at each period is dominated by the rule-based conjectures, despite the existence

of the case-based conjectures. To guarantee that this is the case, we set

$$\phi(\mathcal{R}_t) = \frac{3}{(t+5)^2}$$

at each  $t \geq 0$ .

Observe that, for  $t \geq 0$ ,

$$\begin{aligned}\phi(\mathcal{R}_{t+1}) &= \frac{3}{(t+6)^2} \\ \phi(\mathcal{W}_{t+1}) &= \phi(\mathcal{R}_t) - \phi(\mathcal{R}_{t+1}) \\ &= \frac{3}{(t+5)^2} - \frac{3}{(t+6)^2}.\end{aligned}$$

This dictates the definition of  $\phi$  on  $\mathcal{R}$ : we start with  $\phi(\mathcal{R}) = \phi(\mathcal{R}_0) = \frac{3}{5^2}$ , and assign the weight  $3[(t+5)^{-2} - (t+6)^{-2}]$  to the subset of theories  $\mathcal{W}_{t+1}$ . Since  $\cup_t \mathcal{W}_t = \mathcal{R}$ , this defines  $\phi$  on all of  $\mathcal{R}$ . Clearly,  $\phi(\mathcal{R})$  is finite.

Next, observe that at each  $t \geq 0$ ,  $\omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{A}(h_t, \{y\}))$ . Specifically, at  $t = 0$  we only have to compare the rule-based hypotheses. We have

$$\begin{aligned}\phi(\mathcal{R}_1) &= \frac{3}{6^2} \\ \phi(\mathcal{W}_1) &= \frac{3}{5^2} - \frac{3}{6^2}\end{aligned}$$

so that

$$\phi(\mathcal{R}_1) - \phi(\mathcal{W}_1) = 2\frac{3}{6^2} - \frac{3}{5^2} > 0.$$

For each  $t \geq 1$ , the total weight of the case-based conjectures is

$$t\frac{1}{(t+5)^3}.$$

We wish to show that the weight of the theories that predict the ‘‘correct’’ continuation  $\omega_Y(t)$ ,  $\mathcal{R}_{t+1}$ , is larger than that of the theories that predict other continuations, even when the latter is combined with all case-based conjectures. Indeed,

$$\phi(\mathcal{R}_{t+1}) - \phi(\mathcal{W}_{t+1}) = 2\frac{3}{(t+6)^2} - \frac{3}{(t+5)^2} > t\frac{1}{(t+5)^3}.$$

This completes the proof that  $\omega_Y(t) \in \arg \max_{y \in Y} \phi(\mathcal{A}(h_t, \{y\}))$  for all  $t$ , and it is easily verified that after normalization we obtain  $\phi \in \Phi_+^p$  such that  $\omega \in \Omega_\phi$ .  $\square$

## 6.5 Proof of Proposition 5

Assume that  $\omega \in \mathbb{S}$ . Then there exists a theory  $f \in \mathcal{R}$  such that  $\omega \in [f]$ . Since  $\phi \in \Phi_+$ ,  $\phi(f) > 0$  and this implies that  $\phi(\mathcal{R}(h_t(\omega))) > \phi(f) > 0$  for all  $t$ . By contrast,  $\phi(\mathcal{CB}(h_t(\omega))) \searrow 0$ . Similarly,  $\phi(\mathcal{R}(h_t(\omega)) \setminus \mathcal{R}(h_{t+1}(\omega))) \searrow 0$  because the sets  $\{\mathcal{R}(h_t(\omega)) \setminus \mathcal{R}(h_{t+1}(\omega))\}_t$  are pairwise disjoint (and the sum of their weights is bounded). Hence, from some  $T$  onwards, theory  $f$  dominates prediction and  $\omega \in \Omega_{RB\phi}$ .  $\square$

## 6.6 Proof of Proposition 6

Let there be given  $\phi \in \Phi_+^{cp}$  and assume that  $\omega \in \Omega_{CB\phi}$ . This implies that, from some  $T$  onwards,  $\omega_Y(t)$  can be computed from  $h_t(\omega)$  by an algorithm that mimics the summation of  $\phi$ . Because  $\phi$  itself is computable, there exists a theory  $f \in \mathcal{R}$  such that  $\omega \in [f]$ , and it follows that  $\omega \in \Omega_{RB\phi}$ . Clearly,  $\Omega_{RB\phi} \cap \Omega_{CB\phi} = \emptyset$  and it follows that  $\Omega_{CB\phi} = \emptyset$ .  $\square$
